Abstract

The effects of geometrically imposed three-dimensional disturbances that were introduced by a spanwise-periodic trailing-edge splitter plate on the instantaneous base pressure of a circular cylinder were investigated. Measurements indicate a direct coupling to the shedding frequency between the stagnation-line and base-pressure signals. A low frequency component in the base pressure power spectra was found and was directly related to the rregular shedding observed in the wake.

Introduction

It has been previously shown by Roshko [1,2] that the vortex shedding structure can be altered by the introduction of a splitter plate in the near wake of a circular cylinder. A splitter plate has the effect of modifying the region of absolute instability behind a bluff body and in some cases was observed to either enhance or attenuate vortex strength, Roshko[1] and Gerrard [3]. Use of splitter plates delays any direct interaction between the wo opposing shear layers and lengthens the regions behind the body before vortices are fully formed, Apelt & Isaacs [4], Apelt, West & Szewczyk [5], Igarashi [6], Unal & Rockwell [7]. A comparison of the measurements in the wake of a circular cylinder with a wo-dimensional straight splitter plate to those with a spanwise-periodic trailing-edge splitter plate, Pearson & Szewczyk [8], indicates a variation in wake width, formation ength and vortex shedding modes. The present investigation was undertaken to study the effects of a spanwise-periodic trailing-edge splitter plate on the instantaneous fluctuating base pressures

dimensional splitter plates of varying length as well as spanwise-periodic trailing-edge splitter plates of varying length, amplitude and wavelength. All splitter plates were 1.6 mm as well as varying amplitude, a/D = 0.5, 0.875, 1.875, and constant plate length and 1.0, 1.5 and 2.0. Spanwise-periodic trailing-edge splitter plates of varying plate length, ℓ/D = 0.625, 1, 2, and constant amplitude and wavelength, a/D=0.5 and $\lambda/D=3$ respectively, wavelength, $\ell/D = 2$ and $\lambda/D = 3$ respectively were studied. Peaks and valleys were designated as the splitter plate positions with the most downstream and upstream trailing edge respectively. End plates were used in all experiments and had a 2.5 aspect ratio as recommended by Stansby [9]. The end plates were slotted to accommodate a splitter plate thick. The two-dimensional plates had length to diameter ratios of $\ell/D=0.125, 0.5, 0.625,$ and mounted such that the length-to-diameter ratio was 8.

The model was equipped with flush mounted pressure transducers along the stagnation line and in the base region, at 170 degrees relative to the stagnation line, see Fig. 1. Calibrated pressure transducers had a range of 0-10 inches of H2O, a sensitivity of 5mv/in H2O, a frequency response of 50 kHz and a linear response up to 2.5 kPa.

The shedding characteristics from the model were detected with a hot-wire probe using a TSI Flow Analyzer IFA-100. Data acquisition of velocity and pressure signals as well as control of a three-dimensional traverse unit for the probe was performed through a Macintosh IIfx computer with LABView hardware and software. The system had the capability of sampling eight simultaneous signals at a rate of 250 kHz per channel

Experimental Results

Tests were conducted at Reynolds number of 30,000 in the wind tunnel and with model described above. Unsteady pressure measurements were made at several spanwise locations along the stagnation line and in the base region. Long time averages of the pressure signals were found to be in good agreement with other mean pressure measurements previously reported by Apelt et al.[4, 5] for two dimensional splitter plates and by Pearson &Szewczyk [8] for spanwise-periodic trailing-edge splitter plates.

plate configurations. Several observations can be made about the features of the fluctuating Stagnation-line pressure traces, Figs. 2(a-c), were correlated at the shedding frequency, 38.3 Hz and were always in phase with each other. Spanwise base pressure signals from peak and valley locations Figs. 2(d-i), reveal a strong correlation with the 2(d-i). For the equivalent two-dimensional splitter plates, Figs. 2(f-i) similar phase shedding frequency and were always in phase except for phase reversals shown in the Figs. reversals were also observed. These measurements indicate a direct coupling to the correspond to a location of a peak and valley for the periodic splitter plate for all splitter shedding frequency between the stagnation-line and base pressure signals as was observed by Mangalam & Kubendran [9] for a plain circular cylihder. However, no direct feedback of the non-regular phase reversals indicated in Figs. 2(d-i) was found in the stagnation-line a/D=0.5, and λ /D=3.0 and equivalent two-dimensional splitter plates ℓ /D=0.5 and 1.0 are pressure signals. For &/D=0.625 the stagnation-line peak and valley pressure signals were found to be 1800 out of phase with the base pressure signals at the same spanwise location. are located at the same spanwise The transducers તં shown in Fig. pressures.
